## MFE R Programming Workshop Week 6

Brett Dunn and Mahyar Kargar

Fall 2017

#### Introduction

#### Questions

Any questions before we start?

#### Overview

- **>** %>%
- ▶ tidyr
- ▶ dplyr

### The Pipe Operator %>%

- ► The magnittr package provides a pipe operator.
- ► See vignette("magrittr").
- Basic piping:
  - x %>% f is equivalent to f(x)
  - x %>% f(y) is equivalent to f(x, y)
  - x %>% f %>% g %>% h is equivalent to h(g(f(x)))
- ▶ The argument placeholder:
  - x %>% f(y, .) is equivalent to f(y, x)
  - $\rightarrow$  x %>% f(y, z = .) is equivalent to f(y, z = x)

#### Expose the variables with %\$%

► The %\$% allows variable names (e.g. column names) to be used in a function.

```
library(magrittr)
iris %>%
  subset(Sepal.Length > mean(Sepal.Length)) %$%
  cor(Sepal.Length, Sepal.Width)
```

```
## [1] 0.3361992
```

### Compound assignment pipe operations with %<>%

There is also a pipe operator which can be used as shorthand notation in situations where the left-hand side is being "overwritten":

```
iris$Sepal.Length <-
iris$Sepal.Length %>%
sqrt()
```

Use the %<>% operator to avoid the repetition:

```
iris$Sepal.Length %<>% sqrt
```

► This operator works exactly like %>%, except the pipeline assigns the result rather than returning it.

tidyr

#### Hadley Wickham

- ► Hadley Wickham is practically famous in the R world
- ► He's developed a very large number of useful packages, e.g. ggplot2 and lubridate.
- Today we will look at dplyr and tidyr.
- Tidy data is data that's easy to work with: it's easy to munge (with dplyr), visualise (with ggplot2 or ggvis) and model (with R's hundreds of modelling packages).
- ▶ The two most important properties of tidy data are:
  - ► Each column is a variable.
  - Each row is an observation.
- Check R for Data Science book.

#### Sample data

- ▶ A common problem is a dataset where some of the column names are not names of variables, but values of a variable.
- ► Take table4a: the column names 1999 and 2000 represent values of the year variable, and each row represents two observations, not one.
- tidyr is a member of the core tidyverse.

```
library(tidyverse)
table4a
```

```
## # A tibble: 3 × 3
## country `1999` `2000`
## * <chr> <int> <int> <int>
## 1 Afghanistan 745 2666
## 2 Brazil 37737 80488
## 3 China 212258 213766
```

#### Bring columns together with gather()

- ➤ To tidy a dataset like this, we need to gather those columns into a new pair of variables. To describe that operation we need three parameters:
  - ► The set of columns that represent values, not variables. In this example, those are the columns 1999 and 2000.
  - ► The name of the variable whose values form the column names. I call that the key, and here it is year.
  - ► The name of the variable whose values are spread over the cells. I call that value, and here it's the number of cases.

#### Bring columns together with gather()

▶ In the final result, the gathered columns are dropped, and we get new key and value columns.

```
table4a %>%
  gather(`1999`, `2000`, key = "year", value = "cases")
## # A tibble: 6 × 3
##
        country year cases
##
          <chr> <chr> <int>
  1 Afghanistan 1999
                         745
         Brazil 1999 37737
## 2
## 3
          China 1999 212258
  4 Afghanistan 2000 2666
## 5
         Brazil 2000 80488
## 6
          China 2000 213766
```

#### Split a column with spread()

- Spreading is the opposite of gathering. You use it when an observation is scattered across multiple rows.
- ► For example, take table2: an observation is a country in a year, but each observation is spread across two rows.

#### table2

```
# A tibble: 12 \times 4
##
          country
                    year
                                type
                                          count
##
            <chr> <int>
                               <chr>
                                          <int>
                    1999
                                            745
##
  1
      Afghanistan
                               cases
## 2
      Afghanistan
                   1999 population
                                       19987071
                    2000
                                           2666
##
  3
      Afghanistan
                               cases
                    2000 population
##
   4
      Afghanistan
                                       20595360
                                          37737
## 5
           Brazil
                    1999
                               cases
## 6
           Brazil
                    1999 population
                                      172006362
## 7
           Brazil
                    2000
                                          80488
                               cases
           Brazil
                    2000 population
                                      174504898
## 8
```

#### spreading

- ➤ To tidy this up, we first analyse the representation in similar way to gather(). This time, however, we only need two parameters:
  - ► The column that contains variable names, the key column. Here, it's type.
  - ► The column that contains values forms multiple variables, the value column. Here it's count.

#### spreading

Once we've figured that out, we can use spread(), as shown below

```
spread(table2, key = type, value = count)
```

```
## # A tibble: 6 × 4
        country year cases population
##
          <chr> <int> <int>
                                 <int>
## *
                1999
                        745 19987071
   1 Afghanistan
  2 Afghanistan 2000 2666 20595360
## 3
         Brazil 1999
                      37737 172006362
         Brazil 2000 80488 174504898
## 4
## 5
          China 1999 212258 1272915272
          China 2000 213766 1280428583
## 6
```

#### spread() and gather() are complements

```
df \leftarrow data.frame(x = c("a", "b"), y = c(3, 4),
                 z = c(5, 6)
df
## x y z
## 1 a 3 5
## 2 b 4 6
df %>% spread(x, y) %>% gather(x, y, a:b, na.rm = TRUE)
## z x y
## 1 5 a 3
## 4 6 b 4
```

#### There's much more

- ► As usual, read the vignette on the CRAN page.
- ▶ Also check Chapter 12 of R for Data Science book.

dplyr

#### Overview of dplyr

- dplyr provides a grammar of data manipulation.
  - ► A simple way to interact with data.
- We learn about:
  - ▶ tibble structure tbl
  - ► The pipe operator %>%
  - Using dplyr with databases
- ► The dplyr introduction vignette is a good resource.

#### dplyr and data.table

- ► See this post.
- Here are my thoughts:
  - ► For data less than 1 million rows, it is reported that there is not a significant speed difference between the two.
  - ▶ For large data that can fit in memory, use data.table.
  - For data than cannot fit in memory, you could use dplyr with a database backend.
- dtplyr is a package to use dplyr with data.table.
  - ▶ It is slower than just using data.table.

#### Data: nycflights13

## # A tibble: 4 × 19

- ► To explore the basic data manipulation verbs of dplyr, we'll start with the built in nycflights13 data frame
- ► This dataset contains all flights that departed from New York City in 2013.

```
library(dplyr)
library(nycflights13)
head(flights,4)
```

```
## year month day dep_time sched_dep_time dep_delay
## <int> <int> <int> <int> <dbl>
```

```
## 1 2013 1 1 517 515 2
## 2 2013 1 1 533 529 4
## 3 2013 1 1 542 540 2
```

## 4 2013 1 1 544 545 -1
## # ... with 13 more variables: arr\_time <int>,
## # sched arr time <int>, arr delay <dbl>, carrier <chr:

#### tbls (Tibbles)

- dplyr can work with data frames as is, but if you're dealing with large data, it's worthwhile to convert them to a tbl df.
- ▶ A tbl will only display the data that will fit in your console. -glimpse() is another nice way to look at the data

```
flights <- tbl_df(flights)
flights
```

```
# A tibble: 336,776 × 19
##
      year month day dep_time sched_dep_time dep_delay
     <int> <int> <int>
                                                  <dbl>
##
                          <int>
                                        <int>
```

## 1	2013	1	1	517	515	2
## 2	2013	1	1	533	529	4
## 3	2013	1	1	542	540	2
	0040			E 4 4	E 4 E	-

## 4	2013	1	1	544	545	-1
## 5	2013	1	1	554	600	-6

-1	545	544	1	1	2013	4	##
-6	600	554	1	1	2013	5	##
-4	558	554	1	1	2013	6	##
23 <del>7</del> <b>5</b> 8	600	555	1	1	2013	7	##

#### Single Table Verbs

- dplyr aims to provide a function for each basic verb of data manipulation:
- select() (and rename())
  - returns a subset of the columns
- filter() (and slice())
  - returns a subset of the rows
- arrange() reorders rows
  - reorders the rows according to single or multiple variables
- distinct()
- mutate() (and transmute())
  - builds adds new columns from the data
- summarise() calculates summary statistics
  - which reduces each group to a single row by calculating aggregate measures
- sample\_n() and sample\_frac()

#### Tidy Data

- dplyr works best with tidy data. i.e. when variables are in columns and observations are in rows.
- ► As shown above, you can use tidyr to help you create a tidy dataset.

#### Select Columns by Name with select()

select() allows you to rapidly zoom in on a useful subset using operations that usually only work on numeric variable positions:

```
# Select columns by name
select(flights, year, month, day)
```

```
## # A tibble: 336,776 × 3
##
      year month
                  dav
##
     <int> <int> <int>
## 1
      2013
## 2 2013
## 3 2013 1
      2013 1
## 4
## 5
      2013
## 6
      2013
## 7
      2013
      2013
```

#### Select a Range of Columns with:

```
# Select all columns between year and day (inclusive) select(flights, year:day)
```

```
## # A tibble: 336,776 × 3
##
      year month
                  day
## <int> <int> <int>
## 1
    2013
## 2 2013
## 3 2013 1
    2013 1
## 4
## 5
      2013
## 6
      2013
      2013
## 7
      2013
## 8
      2013
## 9
## 10
      2013
  # ... with 336,766 more rows
```

### An Example of -(col1:col2)

600

600

600

... with 336,766 more rows, and 12 more variables:

sched arr time (int) arr delay (dhl) carrier (chr)

#### select Helper Functions

- dplyr comes with a set of helper functions that can help you select groups of variables inside a select() call:
- starts\_with("X"): every name that starts with "X",
- ▶ ends\_with("X"): every name that ends with "X",
- contains("X"): every name that contains "X",
- matches("X"): every name that matches "X", where "X" can be a regular expression,
- num\_range("x", 1:5): the variables named x01, x02, x03, x04 and x05,
- one\_of(x): every name that appears in x, which should be a character vector.

#### Add New Columns with mutate()

```
flights %>% mutate(
    gain = arr_delay - dep_delay,
    speed = distance / air_time * 60) %>%
    select(year,month,gain,speed)
```

```
## # A tibble: 336,776 × 4
##
      year month gain speed
     <int> <int> <dbl>
                       <dbl>

540

-3

-2

#### Select rows by position

► To select rows by position, use slice()

```
slice(flights, 1:10)
```

```
# A tibble: 10 × 19
##
                      day dep_time sched_dep_time dep_delay
       vear month
##
      <int> <int> <int>
                              <int>
                                              <int>

## #
       arr time <int>, sched arr time <int>, arr delay <db
```

carrier (chr) flight (int) tail num (chr)

year month day dep time sched dep time dep delay

#### Extract unique rows with distinct

- ▶ A common use of select() is to find the values of a set of variables.
- ► This is particularly useful in conjunction with the distinct() verb

```
distinct(select(flights, tailnum))
```

```
## # A tibble: 4,044 × 1
##
      tailnum
##
        <chr>
    N14228
## 1
## 2 N24211
## 3
       N619AA
## 4
       N804.JB
       N668DN
## 5
## 6
       N39463
## 7
       N516.JB
       N829AS
##
```

#### Summarise values with summarise()

- The last verb is summarise(). It collapses a data frame to a single row.
- ► You can use any function you like in summarise() so long as the function can take a vector of data and return a single number.

```
flights %>% summarise(
          delay = mean(dep_delay, na.rm = TRUE))
```

```
## # A tibble: 1 × 1
## delay
## <dbl>
## 1 12.63907
```

### dplyr aggregate functions

- dplyr provides several helpful aggregate functions of its own, in addition to the ones that are already defined in R. These include:
  - ▶ first(x) The first element of vector x.
  - ▶ last(x) The last element of vector x.
  - nth(x, n) The nth element of vector x.
  - n() The number of rows in the data.frame or group of observations that summarise() describes.
  - ▶ n\_distinct(x) The number of unique values in vector x.

## Chaining

- The dplyr API is functional function calls don't have side-effects.
- You must always save their results. UGLY
- ▶ To get around this problem, dplyr provides the %>% operator
- $\triangleright$  x %>% f(y) turns into f(x, y)

## Chaining example

```
flights %>%
group_by(year, month, day) %>%
select(arr_delay, dep_delay) %>%
summarise(arr = mean(arr_delay, na.rm = TRUE),
dep = mean(dep_delay, na.rm = TRUE)) %>%
filter(arr > 30 | dep > 30)
## Source: local data frame [49 x 5]
## Groups: year, month [11]
##
##
      year month day
                          arr
                                  dep
##
     <int> <int> <int> <dbl> <dbl>
## 1
    2013 1 16 34.24736 24.61287
## 2 2013 1 31 32.60285 28.65836
## 3 2013 2 11 36.29009 39.07360
    2013 2
## 4
                   27 31.25249 37.76327
## 5
      2013 3
                    8 85.86216 83.53692
              3
## 6
      2013
                   18 41 29189 30 11796
```

#### **Commonalities**

- ▶ The syntax and function of all these verbs are very similar:
- ▶ The first argument is a data frame.
- ► The subsequent arguments describe what to do with the data frame.
- The result is a new data frame
- ► Together these properties make it easy to chain together multiple simple steps to achieve a complex result.

### **Grouped operations**

- ► These verbs are useful on their own, but they become really powerful when you apply them to groups of observations
- ▶ In dplyr, you do this by with the group\_by() function.
- ▶ It breaks down a dataset into specified groups of rows.

# Grouped operations (cont.)

- Grouping affects the verbs as follows:
- grouped select() is the same as ungrouped select(), except that grouping variables are always retained.
- grouped arrange() orders first by the grouping variables
- mutate() and filter() are most useful in conjunction with window functions (like rank(), or min(x) = ). They are described in detail in vignette("window-functions").
- sample\_n() and sample\_frac() sample the specified number/fraction of rows in each group.
- slice() extracts rows within each group.
- summarise() is powerful and easy to understand, as described in more detail below.

### group\_by Example

► For example, we could use these to find the number of planes and the number of flights that go to each possible destination:

```
## # A tibble: 105 × 3
##
      dest planes flights
##
     <chr> <int>
                    <int>
## 1
       ABQ
              108
                      254
## 2
       ACK 58
                      265
## 3
       ALB
           172
                      439
       ANC
                        8
## 4
                6
       ATT.
## 5
             1180
                    17215
##
       AUS
              993
                     2439
       AVT.
              159
                      275
##
```

### Multiple table verbs

- dplyr implements the four most useful SQL joins:
  - ▶ inner\_join(x, y): matching x + y
  - ▶ left\_join(x, y): all x + matching y
  - semi\_join(x, y): all x with match in y
  - anti\_join(x, y): all x without match in y
- And provides methods for:
  - intersect(x, y): all rows in both x and y
  - ▶ union(x, y): rows in either x or y
  - setdiff(x, y): rows in x, but not y

# Joins from dplyr Map to SQL

- ▶ inner\_join(x, y)
  - ► SELECT \* FROM x JOIN y ON x.a = y.a
- ▶ left\_join(x, y)
  - ► SELECT \* FROM x LEFT JOIN y ON x.a = y.a
- ► right\_join(x, y)
  - ► SELECT \* FROM x RIGHT JOIN y ON x.a = y.a
- ► full\_join(x, y)
  - ► SELECT \* FROM x FULL JOIN y ON x.a = y.a
- semi\_join(x, y)
  - ► SELECT \* FROM x WHERE EXISTS (SELECT 1 FROM y WHERE x.a = y.a)
- ▶ anti\_join(x, y)
  - ► SELECT \* FROM x WHERE NOT EXISTS (SELECT 1 FROM y WHERE x.a = y.a)

#### Lab 3

▶ Let's redo Lab 3 with dplyr.
